Abstract: This study uses data from 2008 to 2019 to investigate the possibility that the macroeconomic news announcements are causing inconsistent price shocks to exchange rates. The evolution of these price shocks is thereafter estimated when it is presumed there is instability over time. Separate methodologies from past literature are applied to the data and compared to one another. In addition we juxtapose the the methods with our objective and evaluate their use.

1 Introduction

Some macroeconomic figures used to gauge the health of a nation’s economy are released to the public on a predetermined schedule. These include for example the Non-Farm Employment change that is released on the first Friday of every month informing economists and investors alike of the status of employment in the United States.

Economic theory helps us understand that an increase of interest rates is warranted when economies are performing well and prices are generally increasing. The authorities who decide to increase or decrease national interest rates, the central banks, typically refer to measures of inflation in order to make their decisions. Because of this, investors and traders alike pay close attention to news releases (such as inflation, and also the Non-Farm-Payrolls in the case of the United States) and react according to the results. These news releases are not made public until specific times on specific days and since investors and traders react to the same news the moment it is released, the result is often a violent reaction of price in one direction or another. The common belief is that the direction and the magnitude of the change of price depends on the difference between the expectation of the market (combined expectation of worldwide investors) and the actual result of the news release.

In this paper, we decide to use currency pairs to measure the price shocks. As certain news pertaining to a particular country affects its respective currency, it makes sense to observe the currency most relevant to the news announcement. As currency prices are typically measured in pairs, the second chosen currency will be another major currency that is known for its high liquidity (EUR, USD or CHF) and does not have any other news announcements at the same time¹. As an example, we would use the USD/CAD currency pair to measure the effect of the Canadian Consumer Price Index (CPI).

The paper of Andersen et al. (2003) reveals that over the time period between 1987 and 2002 there has been little time-variation in the reaction to news. A more recently published paper of Ben Omrane et al. (2019) involving an analysis on euro-dollar contracts has determined that unlike the decade(s) encompassing the “Great Moderation”, where there was lower relative volatility in the financial markets, the time period between 2004 and 2014 is characterized by time-varying reactions to macroeconomic news.

The objective of this paper is twofold. First, we aim to employ existing methodologies on new data to identify whether or not instability of market reaction is present. Second, when reactions do change over time, we attempt to estimate the path that it takes using different procedures suggested by the literature, given that the instability has been identified.

2 Data

The minute-by-minute OHLC data of 7 currency pairs were collected from the Metatrader5 platform between 2008 and the end of 2019. This represents over 4 million data points for each currency pair considered in the study. Only a small fraction of this data is actually used since we only consider the 5 minute window after the release of monthly or quarterly news. Regarding the collection of macroeconomic figures data, the expectation numbers from the ForexFactory website were used². The process of combining of the two separate datasets was complex and involved careful consideration of erratic scheduling changes of the organizations releasing the figures, as well as the daylight savings and timezones of all considered data.

3 Building blocks of the models

3.1 The Stable Linear Model that is Time Invariant

Being consistent with previous literature on the subject, the first step involves estimating the impact that each piece of news has on its respective currency assuming 1.) That the news effects are constant over time,

¹When simultaneous news cannot be avoided, a sequence of stability tests will be applied to ensure time variation is identified on a specific news release. Alternatively, when simultaneous news for two announcements occur at the same time but only for a fraction of the sample, those observations are omitted (this was the case for the Canadian Retail Sales and Consumer Price Index).

²The expectations of most online sources such as “Investing.com” or “DailyFX” are very similar. Unfortunately, the aggregation methods are not disclosed to the public.

Figure 1: Minute-by-minute candlechart of the USD/CAD asset on the 19th of June between 15h00 and 16h00 GMT+2. An example of the sudden price change that can occur during one of the news releases. Green/Red candles represent an increase/decrease in price. The gray indicator is amount of trading activity taking place (a rough guideline as it only includes transactions from that particular brokerage).

Table 1: Summary of the news figures considered in the study

Country	News.Event	Pair.used	GMT.Time	Frequency	Observations	Dates
Single News						.
Canada	Consumer Price Index	USD/CAD	13:30	Monthly	103	Jan 2008 to Dec 2019
Canada	Core Retail Sales	USD/CAD	12:30	Monthly	94	Oct 2008 to Dec 2019
United States	Consumer Price Index	USD/CHF	13:30	Monthly	135	Oct 2008 to Dec 2019
New Zealand	Consumer Price Index	NZD/USD	21:45	Quarterly	43	Jan 2009 to Oct 2019
Australia	Consumer Price Index	AUD/USD	00:30	Quarterly	48	Jan 2008 to Oct 2019
Australia	Retail Sales	AUD/USD	00:30	Monthly	135	Oct 2008 to Dec 2019
United Kingdom	Consumer Price Index	GBP/USD	09:30	Monthly	135	Oct 2008 to Dec 2019
United Kingdom	Retail Sales	GBP/USD	09:30	Monthly	135	Oct 2008 to Dec 2019
Grouped News						.
United States	Average Hourly Earnings Change	USD/CHF	13:30	Monthly	135	Oct 2008 to Dec 2019
United States	NonFarm Employment Change	USD/CHF	13:30	Monthly	135	Oct 2008 to Dec 2019
United States	Unemployment Rate	USD/CHF	13:30	Monthly	135	Oct 2008 to Dec 2019
Canada	Employment Change	USD/CAD	13:30	Monthly	135	Oct 2008 to Dec 2019
Canada	Unemployment Rate	USD/CAD	13:30	Monthly	135	Oct 2008 to Dec 2019
Australia	Employment Change	AUD/USD	00:30	Monthly	135	Oct 2008 to Dec 2019
Australia	Unemployment Rate	AUD/USD	00:30	Monthly	135	Oct 2008 to Dec 2019

Note: The Canadian Consumer Price Index and Core Retail Sales coincided in Date and Time 41 times and these observations were removed.

Note: The result of OLS estimation, referred to as the 'time invariant' or 'stable' case is presented in this table. The standard errors of the estimator as well as the Newey-West corrected standard errors are also included. The *, **, *** are for 10%, 5% and 1% significance levels respectively.

2.) The surprise element S_t of the regression is evaluated as:

$$S_t = \frac{A_t - E_t}{\sigma_d} \quad (1)$$

A_t is the actual result of the news at time t , E_t is the expected result aggregated from experts and σ_d is the empirical standard deviation of their difference over the entire sample. Thereafter, we use this surprise element in a first simple OLS model.

$$R_t = \beta_0 + \beta_1 S_t + \varepsilon_t \quad (2)$$

With R_t as the 5-minute currency return result and ε_t as the usual error, assumed to be normally distributed. Moreover, because we are working with a dataset where subsequent observations are suspected to be related to one another, one could expect that the errors of the basic model above be autocorrelated. Specifically, adjacent R_t would be more similar to one another than reactions that are further detached in time. In this case, the inference on the β_1 would be flawed. Previous researchers have used what is called Heteroskedasticity and Autocorrelation-Consistent (HAC) estimators for the variance of the OLS estimator β_1 . Using the Newey-West estimator for this variance from Newey and West (1987), we use modified standard errors of the β_1 in our results. If we are wrong in our assumption in some of the news instances, and there is no underlying autocorrelation of the R_t observations, our estimation of β_1 is less efficient than the original estimator in those cases. Nonetheless, it remains consistent and ensures we avoid type 1 error of rejecting a true null hypothesis suggesting $\beta_1 = 0$.

Table 2 shows the result of the different β_1 coefficients for separate news reports. The construction of the truncation parameter in the Newey-West estimator is such that our monthly news reports consider 2

autocorrelation coefficients whereas the quarterly ones only contain 1. This is due to the difference in the number of observations in our data. A higher estimated autocorrelation between the errors of the regression will result in a stronger correction of the variance of β_1 . In all of the news in Table 2, the higher standard error does not affect the significance of the term. While it is not formal evidence, we suspect that the regressions where the HAC standard error is larger than its unedited counterpart contain unknown regressors that may come from any of the findings that are well expanded on in other literature such as in Goldberg and Grisse (2013). Overall, these results and that of the Durbin-Watson test show that there is little evidence for significant autocorrelation in the residuals.

3.2 The Gaussian Random Walk

The methods discussed in this paper use Gaussian Random Walks (GRW) extensively. This section serves to underline the features of these processes which will later be essential to the understanding of tests and path estimations. Furthermore, it hopefully helps one fully appreciate the assumptions that will be made when using them and how these processes can be used to help decipher the variation of the β_t .

The GRW is a sequence of *i.i.d* random variables where one realization at time t follows the distribution:

$$X_t \sim \mathcal{N}(\mu_t, \sigma_t^2) \quad (3)$$

Using the independence assumption of normally distributed random variables, their sum and the distribution of their sum is then given by (4).

$$U = \sum_{t=1}^T X_t, \quad U \sim \mathcal{N}(\mu_t T, \sigma_t^2 T) \quad (4)$$

In theory the path that β takes could resemble any of the paths in Figure 2. The process depicted by Y2 is a baseline case where the parameter would not vary in time. The Y3 process is a random walk with $\mu = 0$ and a fixed σ which is in reality the same as white noise. The Y1 is a random walk with a constant negative μ . Finally, the Y4 process depicts a scenario with one significant break in the path of β_t and is the combination of 2 separate random walks with separate constant μ and σ . Within the context of our problem, it is important to consider all of these possibilities, as the potential evolution in the reactions could be erratic in nature (frequent and haphazard change), or gradual (slow and constant change) over time. We would like to detect the changes regardless of the scenario.

4 Testing for instability of the news impact parameter

4.1 The quasi-Local-Level Test

There exists many ways to test whether β_t is time dependent or not. We first choose the methodology of Elliott and Müller (2006) and replicate their method. The advantage of their test is that it identifies instability no matter whether it comes in the form of a single break, many breaks, or a continuous change (all of which are feasibly possible in the context of our investigation). Furthermore, the result of the Monte Carlo simulations over different processes also showed that, compared to other tests that exist, the qLL test has the most power in smaller samples.

The quasi-Local-Level (qLL) test enables one to test for many different types of persistent processes of β_t . It is explained that many of these breaking processes can have a “temporary memory” (strictly speaking are strongly mixing) but will be well approximated by a Wiener process³. This is extremely practical in our scenario as there are many possibilities for the possible variation of β_t . Under the null hypothesis, the parameter is stable, as in a familiar OLS regression. We obtain the likelihood under the null assuming that the R_t observations are independently and identically distributed (and therefore so are their first differences):

³Theorem 7.30 of (White 2001) can be applied since certain assumptions are made about the process

Note: Results of the three instability tests performed for each piece of macroeconomic news. Multiple tests were performed for some news that occurred simultaneously because the tests are able to detect instability but not pinpoint the exact source of instability for more than 1 figure. The n.s, *, **, *** are for non-significant, 10%, 5% and 1% levels of significance respectively.

Table 4: Asymptotic Critical Values of the qLL Statistic

k	1	2	3	4	5
1%	-11.05	-17.57	-23.42	-29.18	-35.09
5%	-8.36	-14.32	-19.84	-25.28	-30.60
10%	-7.14	-12.80	-18.07	-23.37	-28.55

Note: Extract of the critical values of the qLL Statistic. k represents the number of potential unstable coefficients (number of parameters in the model) whereas 1%, 5% and 10% are the significance levels where a lower value is stronger evidence that instability is present.

$$L_{H0}(\beta_0, \beta_1, \sigma^2) = \log \prod_{t=1}^T p(\Delta R_t | S_t; \beta_0, \beta_1, \sigma^2) \quad (5)$$

$$= -\frac{T}{2} \log(2\pi) - T \log(\sigma) - \frac{1}{2\sigma^2} \sum_{t=1}^T (\Delta R_t - (\Delta\beta_0 + \Delta\beta_1 S_t))^2 \quad (6)$$

Only the last term of (6) is kept as the first constants will cancel out. $\Delta\beta_0 + \Delta\beta_1 S_t$ becomes 0 as the terms do not change with time.

$$L_{H0} = -\frac{1}{2\sigma^2} \sum_{t=1}^T (\Delta R_t)^2 \quad (7)$$

This contrasts with the alternative where instability is implied. We assume $\beta_t - \beta_0$ is approximated by the Gaussian random walk and ΔR_t is therefore a Gaussian moving average of order MA(1) with the specification: $\Delta R_t \sim \eta_t + \psi_\eta \eta_{t-1}$, $\eta_t \sim iidN(0, \sigma_\eta^2)$, constant $\psi_\eta < 1$. Using the same *i.i.d* assumption we obtain the likelihood of this alternative process:

$$L_{HA} = -\frac{1}{2\sigma^2} \sum_{t=1}^T \eta^2 \quad (8)$$

The qLL statistic is obtained by subtracting L_{H0} from L_{HA} : $\frac{\sigma_\epsilon^2}{\sigma_\eta^2} \sum_{t=1}^T \eta^2 - \sum_{t=1}^T (\Delta R_t)^2$. The test is therefore a variant of the Likelihood Ratio Test (LR_T), so while it does not follow a chi-square distribution exactly, it does follow a certain related distribution that has its percentiles defined by Elliott and Müller (2006) and reported in their table, reproduced here as Table 4. The general extension to the LR_T can be made where we can reject the model related to the null hypothesis (the stable model) if the critical value is sufficiently negative. The η term is obtained with additional matrix algebra and regressions as in Elliott and Müller (2006). The appropriate steps are available in Appendix Section 7.4. While it is true that the underlying process can follow many different kinds of processes that could be very complex, we can detect their presence if we allow for their path to be approximated by a GRW (equivalent to having their first difference follow an MA(1)).

4.2 CUSUM and CUSUM-squared tests

Alternatives to the qLL test previously explained are considered. We explore the ones mentioned in Brown, Durbin, and Evans (1975) named the CUSUM and CUSUM-squared. These tests use the successive error terms of predictions of a standard Recursive-Least-Squares (RLS) model (details for this model in Section 9.2), that assumes stability of the β parameter (Young 2011). In this specific application, we use the result of the standard OLS as a baseline *prior* or initial value for the algorithm (i.e. β_0) and we use an empirical $\hat{\sigma}_\epsilon$ residual error that is based on the entire sample. By examining the prediction errors, one can observe whether or not they violate the $\mathcal{N}(0, \sigma^2)$ assumptions. Namely that they are a 1.) zero mean sequence $E(\varepsilon_t) = 0$ and 2.) serially uncorrelated $E(\varepsilon_t \varepsilon_j) = 0 \forall t \neq j$. The first step consists in running a standard RLS algorithm and obtaining one-step-ahead errors from it. These errors are obtained as follows:

$$u_t = R_t - E(\hat{R}_t | R_{t-1}) \quad (9)$$

Effectively the realized price shock minus the predicted price shock at each observation. A transformation of these errors enables us to obtain a homoscedastic series:

$$u_{n,t} = \frac{u_t}{(1 + S_t^T P_t S_t)^{0.5}} \quad (10)$$

Where P_t is the covariance (or variance if there is only one news element at a time) of β_t . A new series is summed up and standardized for use in the CUSUM test.

$$W_t = \frac{1}{\hat{\sigma}_{cs}} \sum_{i=k+1}^t u_{n,i} \quad (11)$$

In theory, these successively compounded errors should not stray too far from the zero-line if the true β_t is constant. We also use the confidence bands suggested by Brown, Durbin, and Evans (1975). They are constructed by constructing pairs of lines starting at time k : $\pm a(T-k)^{0.5}$ and ending at time T : $\pm 3a(T-k)^{0.5}$

CUSUM Test applied to UK CPI

The second test, the CUSUM-squared, can be run by once more by creating a new series, similar to W_t from earlier. Here we consider:

$$V_t = \frac{\sum_{i=k+1}^t u_{n,i}}{\sum_{i=k+1}^T u_{n,i}} \quad (12)$$

Under a null hypothesis of a constant parameter(s), this cumulative sum of squares follow a beta distribution and its mean is $(k-h)/(N-h)$. As significance levels, we use the bounds set as $\pm c_0 + (k-h)/(N-h)$. The values of c_0 depend on the sample size. Our sample sizes are typically larger than the maximum value given in Brown, Durbin, and Evans (1975). For those particular samples, the maximum value was used.

5 Parameter Path Estimations

Having established that there is instability over time in the market reactions to at least some of the news, we take on the task of obtaining a time series that conveys the change over the time frame considered. Specifically, we would like to obtain a visual representation of the change of the parameter such that a researcher or investor is able to easily gather information.

In this section, we will utilize two different algorithms from the literature. Both make different assumptions and are useful to help understand the possible sources of instability, to compare the different announcements and to make short-term forecasts. However, the fundamental difference is that the WAR estimation uses the entire sample while the “simpler” STVP will only use outcomes that occurred in the past for its estimation. Both consider the following unstable time series model:

$$R_t = \beta_0 + \beta_{1,t}S_t + \varepsilon_t \quad (13)$$

5.1 Weighted Average Risk Minimization (WAR)

Conveniently, this method is somewhat of a natural extended use of the qLL test elaborated on in Section 4.1. It provides a heuristic means to approximate a parameter path (Müller and Petalas 2010).

First, we consider our stable model which is analogous to the linear regression model that is presented in the Equation (2). The resulting $\beta_{MLE/OLS}$ parameter obtained either through maximum likelihood estimation or minimization of ordinary least squares (depicted as the dot-dashed line in Figure 3) is representative of a scenario where it is assumed there is no time-related evolution of market reaction to news. As seen before, the likelihood in this case can be developed as equation (5) or also written more generally as $\sum_{t=1}^T l_t(\theta)$ with θ containing the constant parameters.

We then turn to the case of the varying β_t parameter and its associated unstable model. Here, the general likelihood is the same but with time varying parameter(s) contained in $\theta_t = \theta + \delta_t$ with $t = 1, \dots, T$. The δ_t can be imagined as the vertical distances in Figure 3 between the constant β case and the *true* parameter path at time t that is unknown and that we are attempting to estimate. The main argument for the method is that this general likelihood function for a time varying model can be approximated by a second-order Taylor expansion of the likelihood function around $\beta_{OLS/MLE}$ and as a result an approximate estimate of the δ_t term mentioned earlier is obtainable. Effectively it is demonstrated in Müller and Petalas (2010) that the approximation of the log-likelihood function of the parameter path can be restructured such that a log-likelihood function of a Gaussian random variable is recognizable and it is possible to obtain a “pseudo model” as:

$$\beta_{MLE} = \beta_t + T^{-1/2} \hat{H}^{-1} v_0 \quad (14)$$

$$s_t(\beta) = \hat{H} \delta_t + v_t, t = 1, \dots, T \quad (15)$$

\hat{H} is the Hessian of the stable model likelihood divided by the sample size T , s_t is the score function for the stable model. The exact derivations to obtain (15) from the Taylor expansion are described in Müller and Petalas (2010). The δ_t vertical distances can be isolated in the latter expression as all the other elements are available to us.

To use the model of the authors and apply it to our case, we find expressions for s_t and \hat{H} . Essentially, the score function s_t and Hessian \hat{H} can be extracted from the stable linear regression shown in section Section 2 and the likelihood function is therefore the one seen in equation (7). Taking the first and second derivative of the log likelihood with respect to β_1 yields the following two expressions respectively:

$$s_t = \frac{\partial l}{\partial \beta_1} = \sigma^{-2} (R_t - \hat{\beta}_0 - \hat{\beta}_1 S_t) S_t \quad (16)$$

$$\hat{H} = \frac{1}{T} \sum_{t=1}^T h_t(\hat{\beta}) = -\frac{\partial^2 l}{\partial^2 \beta_1^T} = \sigma^{-2} \sum_{t=1}^T S_t^2 \quad (17)$$

In the methodology, we are interested in the score of each particular observation and an *average* of the Hessians. This is why \hat{H} is used instead of h_t in (17). These two estimations, alongside the original β_1 and σ^2 from the time-invariant model are all that is needed to apply the entire WAR algorithm seen in Section 9.3.

Importantly, the score function is measuring the rate of change of the likelihood function with regards to its parameters. In the stable OLS model a lower valued score for a certain observation in a sample indicates that a particular observation decreases the final β_{OLS} estimate. In the WAR minimization method illustrated by our UK CPI example in Figure 3, the scores of the first few observations were mostly negative and led to β_t values below the β_{OLS} . Moreover, we recognize the Fisher Information of the linear regression case when taking the negative expectation of the Hessian (17) or equivalently taking the expectation of the square of (16). Intuitively, the s_t scores therefore provide the vertical direction and a relative distance departure from the β_{OLS} , whereas the \hat{H} Hessian is measuring the *overall* uncertainty of the estimation.

In Figure 3, one can observe 11 different random walk functions as well as the final estimated path for the UK CPI example. While they are all constructed using the scores and Hessian seen in (16) and (17), they each have a unique end point standard deviation. The weights in step (e) of the Appendix Section 7.5 depend on the sample size and the qLL statistic that are obtained using the qLL test statistic from Section 4.1. Specifically, in this step, it can be drawn from the expression $\exp^{-\frac{1}{2} qLL(c_i)}$ that the higher standard deviations in the RW functions lead to a smaller qLL statistic and therefore more importance is placed on the weight associated with that particular RW. However, this is balanced by the preceding expression $\sqrt{T(1 - r_i^2) r_i^{T-1} / (1 - r_i^{2T})}$ that has the opposite effect of simply placing more weight on smaller

RW functions. In our example, the 4th RW function contributes the most weight to the UK CPI final path (green curve in 3).

Figure 3: WAR minimizing over the 11 different random walk weighting functions. The green path, a compromise of the others, is the final path where the loss or is lowest. The dash-dot line is the OLS estimate.

5.2 Standard Recursive Time Variable Parameter Algorithm (STVP)

Until now, the WAR minimization method provided a means to analyze the price reactions to the news over an entire sample period. In practice, it may be more useful to have a self-updating method that iteratively uses every new observation to improve the estimation progressively. The emphasis in this case is placed in gauging investor reactions to news in the present. When building this model, the assumption is that information available at time t includes everything before that moment in time and nothing more, specifically information set \mathcal{F}_{t-1} . This is in contrast with the WAR minimization and is why this particular method is also included.

Starting once more from the baseline case introduced in Section 3, a time-dependent measure of market reaction to news, β_t , can be constructed by 1.) Transforming the problem of OLS so that it can be recursively solved and 2.) Allowing for the parameter(s) to change over time sequentially.

To obtain the STVP algorithm presented in Section 7.3 the first step consists of replacing the OLS equations by their recursive counterparts and obtain the intermediate SRLS algorithm. The following equations are similar to the familiar OLS equations setup but with our variables.

$$R_t = S_t^T \beta_1 + e_t \quad (18)$$

The error vector contains a series of random variables e_t that are assumed to be normally distributed with 0 mean and serially uncorrelated. We omit the constant intercept; the reasoning is explained in Section 7.3.

$$\hat{\beta}_{OLS} = (S^T S)^{-1} S^T R \quad (19)$$

It is implicitly assumed the β does not vary in OLS.

$$\beta_t^{OLS} = \beta_{t-1}^{OLS} \quad \forall t \quad (20)$$

When an observation y_j is added to the samples $i = 1, \dots, N$, an update to $\hat{\beta}$ is the same as re-estimating the entire sample with the new observation. Effectively, the “intermediate model” or Stochastic Recursive Least Squares Algorithm (SRLS) is thereafter obtained (the exact step-by-step is in Section 7.2). While this is a powerful tool, it does not necessarily help us estimate y_j effectively. It gives just as much weight to realizations of y early in the sample as to those that immediately precede the new extra observation j . The contribution of every marginal observation is smaller and smaller as the sample grows. The $\hat{\beta}$ converges to the full sample parameter estimator $\hat{\beta}_{OLS}$ as seen in Figure 4.

Figure 4: SRLS applied to the UK CPI

Additional data points in the aforementioned methodology add information and therefore improve the accuracy of the $\hat{\beta}$ estimator, but it is always assumed that there is only one true β regardless of time t . In order to attenuate this assumption and include the flexibility that allows for a time dependence in β_t , we introduce the random walk disturbance term mentioned in Section 3.2. The error term is now characterized by the

incremental steps of a random walk. In Bayesian terms, the previous estimation of β_t using the random walk becomes the *prior*.

$$R_t = S_t^T \beta_t + e_t, \quad e_t \sim \mathcal{N}(0, \sigma^2) \quad (21)$$

$$\hat{\beta}_t = E(\check{\beta}_t | \hat{\beta}_{t-1}) \quad (22)$$

$$\beta_t = \beta_{t-1} + \eta_{t-1}, \quad \eta_t \sim \mathcal{N}(0, \sigma_\beta^2) \quad (23)$$

When transitioning from the SLRS to STVP method, the setup described by (18), (19) and (20) are replaced by (21), (22) and (23). The latter three STVP equations above are thus the foundation for the construction of the algorithm that is implemented for use and shown in Section 7.3. When initializing the first values, we set the variance of the estimator P_t^* to be very large and the β_t parameter to be 0 to reflect 0 knowledge of the nature of the estimation at the beginning of the sample. The variance σ_β of (23) is set as 25% of the β_{OLS} of the full sample. This is the standard deviation of the random walk *prior* that was deliberately chosen and has important implications in the estimation of the path. Further analysis and review of this choice is covered in Section 6.5

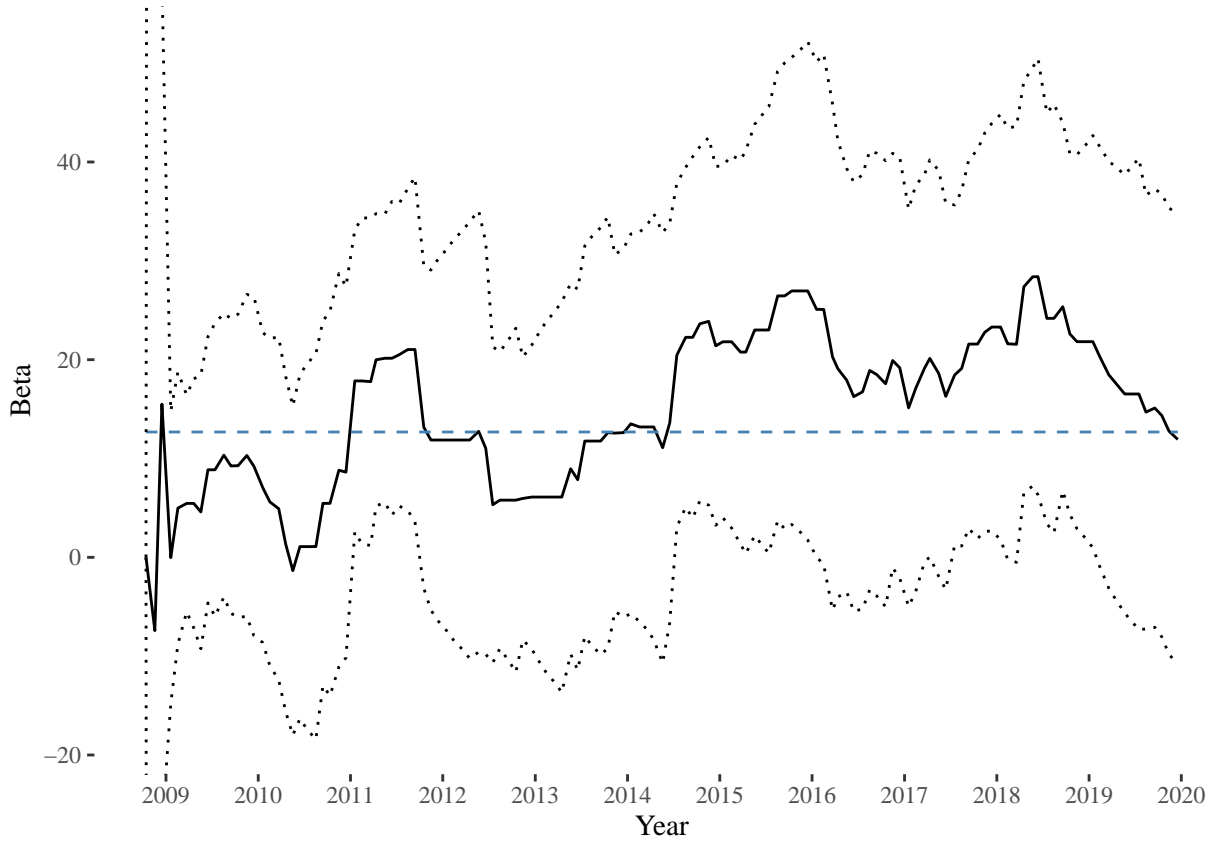

Figure 5: STVP applied to the UK CPI

6 Discussion

6.1 The Three Tests for Instability

Of the three stability tests applied in this study, the qLL test appears to be the most dependable. Notably, unlike the other tests, it is an efficient test statistic that is a monotone transformation of the Likelihood Ratio Test (LRT)⁴ and has asymptotic critical values upon which we can compare the test statistic. Furthermore, it was possible to construct sequential tests in order to detect which news announcement covariate(s) caused the instability by alternating which event is considered “stable” in the test.

On the other hand, the CUSUM and CUSUM-sq tests are comparable to indicators with which it is possible to compare the transformed errors, rather than formal tests (Brown, Durbin, and Evans 1975). However, they do provide the means to analyze the errors so that it is possible to determine at which moment in the sample the instability is taking place. Moreover, because the CUSUM-sq test exposed instability to a much larger degree than the CUSUM for all of the news, it may be an overall trend that there is a changing residual variance. It is important to note that for the CUSUM-sq, the bounds should be even closer to the diagonal beta distribution line than they are as we used the bounds for a sample size of 100 despite having larger samples.

We use the combination of all three tests to determine whether or not instability is present and the paths of β_t parameter of each news event is worth estimating. If at least two of the three tests were significant at the 10% level, their path was estimated using the methodologies presented in 5 and they are illustrated in 7.1.

6.2 Differences and Irregularities of Two Paths

It is quite evident the STVP path is “slower to react” to the changes of its parameter. Informally, the reason for the lag is simply that the method does not benefit from retrospective analysis and is using only previous information to make an estimation. The high credible intervals towards the beginning of the sample are conveying uncertainty.

The WAR Estimation method is especially useful when trying to analyze the evolution of the parameter over the entire sample period. Because of the “forward and backward passes” in the algorithm seen in steps (b) and (c) of section Section 7.5, the beginning of the sample period is estimated with as much precision as its ending. The addition of a reverse order filter means that the resulting estimate is “smoothed over” twice. This is a positive feature because there may occasionally be “noisy” erroneous data points or exceptions due to outside factors that are “smoothed” out by the dictating trend and nearby observations both before and after their occurrence. Moreover, there is an inherent restriction of $\sum_t^T \delta_t = 0$, meaning that the positive δ_t deviations from the average parameter value or β_{OLS} are exactly counterpoised by the negative ones. The path will always have the original, stable, time-invariant estimator as an average.

On the contrary, the STVP estimation is susceptible to exceptional or isolated changes to the price reaction to the macro-announcements at any time during the sample. The β_t path can drastically change when both the surprise S_t shock and the difference $R_t - S_t^T \beta_{t-1}$ are large in absolute terms. A higher noise variance $\hat{\sigma}^2$ (constructed using residual errors) reduces the amount of variation the parameter will take while increasing the distance of the bounds which is undesirable, but reflects the amount of uncertainty there is.

The choice of the random walk prior for both methods is easily scrutinized. On the one hand, there is no limit to the change the parameter can take and the unbounded tails of the normal distribution correctly reflect this property. However, it is highly unlikely, for most news announcements, that the parameter should change in sign and have an inverse effect on price. In other words, it should be assumed that a positive change in retail sales should not result in a negative change in the price and the 0 line should not be breached by the parameter paths.

In the STVP method, using 25% of β_{OLS} to obtain σ_β means that it is very likely the β_t path will end up below 0 early in the sample. However, it also means that negative values for β_t will virtually never occur as soon as the β_t is at or near β_{OLS} and this is why the rule was chosen. Furthermore, the prior formulation

⁴The Neyman-Pearson lemma confirms that the likelihood ratio is the most optimal among other tests

implies that the underlying path follows a GRW when it is not necessarily the case in reality and there may be better priors that reflect the true path. The use of the GRW implies that changes in market reactions to news does not depend on the $\Delta\beta_t$ changes that occurred in the past while an Integrated Random Walk (IRW) would take into account this rate of change for example. In this study, it was assumed that in reality, monthly or quarterly changes $\Delta\beta_t$ were independent.

6.3 Accuracy of the Estimations

Using the Bayesian perspective, the accuracy of the WAR line is measured using 95% posterior probability intervals with the prior being the weighting function of the random walks (Müller and Petalas 2010). Therefore, given that this prior is correct, the β_t lies within the interval zone with a 95% probability. The posterior distribution at each time t , is a weighted compromise of the different random walks and it is the variance of this distribution that is used for the credible intervals see Section 7.6 for its calculation. Conversely, the STVP estimation at time t is achieved using the previous observation estimation at $t - 1$ and the GRW parameters as a prior. One can observe that the STVP estimation bounds are typically much wider than that of the WAR as a result of its larger variance. These bounds are significantly influenced by the choice of the prior standard deviation, and since the latter was chosen rather loosely even if it is considered a “conservative” choice, the bounds are not as sensible as one might expect.

6.4 One-Step ahead Forecasts

While the primary aim of the study was not to obtain forecasts, we investigate the possibility of a naive prediction with their associated prediction intervals. The term *naive* is used because it will be assumed that the best measures for expectation and variance for the 5 minute pip change of \hat{R}_{t+1} are obtained by using the most recent estimates of the sample at time t . Furthermore, using the same example news announcement as previously, we put ourselves in the situation of an investor who has just observed the release of the UK CPI on January 15th 2020 at 11:30:00. We would like a measurement of certainty of where price will lie less than 5 minutes afterwards. Information set \mathcal{F}_t includes all the past event variables whereas S_{t+1} is the new news surprise figure.

$$E(\hat{R}_{t+1}|\mathcal{F}_t, S_{t+1}) = \hat{\beta}_t S_{t+1} \quad (24)$$

$$Var(\hat{R}_{t+1}|\mathcal{F}_t, S_{t+1}) = S_{t+1}^2 \sigma_\beta^2 + \sigma_\epsilon^2 \quad (25)$$

Using the variances for the β_t parameters of each model allows for creation of the two different 95% prediction intervals. These intervals are much wider than the credible intervals considered earlier as there is the additional uncertainty of measurement σ_ϵ^2 or often referred to as the irreducible error. This error is quite large relative to the σ_β^2 , a clear sign that the models could possibly be improved by considering additional predictor variables aside from S_t .

Another example but for the release of the Australian Retail Sales on the 10th of January of the same year shows much wider intervals due to there being less data but also larger variability in the outcome R_t in the sample.

6.5 Use of the Post-Announcement 5 Minute Window

The erroneous or exceptional data can sometimes be quite obvious. An example would be that of the Canadian Core Retail Sales in July of 2013. On this day, the figure achieved a 1.2% increase versus the 0.1% that was expected and yet the 5 minute post-price difference was merely -11.3 pips. The price move was instantaneous to the extent that the beginning of the 14:30:00 candle already marked the majority of the price shock. A solution to this issue would have been to consider using a price before 14:30:00 although this would have introduced the issue of finding a general timing for all other releases that does not include irrelevant price movements before to the announcement time stamp. Furthermore, in some circumstances, it could be

Figure 6: GBP/USD on the 15th of January between 14h00 and 15h00 GMT+2. UK CPI released with a figure of 1.3% versus the expected 1.5% (equivalently a -1.1579697 Std. Dev shock). Point-Estimates and 95% prediction bounds are colored in blue and green for the WAR and STVP estimations respectively. The time-invariant OLS case is also added in black for reference.

Figure 7: AUD/USD on the 10th of January between 02h00 and 03h00 GMT+2. Retail Sales announced at 0.9% versus the expected 0.4% that was expected (equivalently a $+0.8801813$ Std. Dev shock). Point-Estimates and 95% prediction bounds are colored in blue and green for the WAR and STVP estimations respectively. The time-invariant OLS estimate is also added in black for reference.

desirable to omit these price jumps as they would result in what is called “slippage” (a difference between the price an investor will place an order at and the price it is executed at).

Figure 8: USD/CAD on the 27th of July between 14h00 and 15h00 GMT+2. The “missing” data can be attributed to the sudden change in price and lack of liquidity in the moments preceding 14:30:00.

There are several explanations for these exceptions. One example in particular would be market interventions of the central banks which have been proven to occur during or in time proximity to figure releases as shown in studies such as that of Dominguez (2003). Similarly, there is evidence of insider trading preceding news announcements. This is shown in assets such as the E-mini S&P 500 futures where exact order imbalance can be measured. It is perfectly possible that the same kind of activity is taking place in the decentralized currency exchange (or FX) markets (Bernile, Hu, and Tang 2016). It is impossible (or extremely difficult) to detect these external reasons for price shocks and the WAR conveniently “smooths” them over.

It is important to consider that the assets used in this study are well chosen to assess the market reaction to news but they are subject to other factors even during the short 5 minute time frames that are used and this could affect the R_t change in price. Currencies will appreciate or depreciate to a large extent during the day and even during a 5-minute time frame whether or not news is present where $E(\Delta Base/Quote_t) \neq 0$. The use of the smaller time window, despite the shortcomings mentioned above, does allow for the researcher to minimize the amount of “noise” or price movements that are unrelated to the news announcement in theory⁵.

6.6 Suggestions for Future Research

There are many elements that were not accounted for in the model that is first introduced. Despite allowing for time variation, there are many ways to improve upon the initial model. For instance, it has been proven that exchange rate prices may react in an asymmetric fashion where the expectation of a positive price jump is disparate to that of a negative one (Andersen et al. 2003). The magnitude is also affected by the situation of the business cycle for the country from which the news is pertaining to (Fatum, Hutchison, and Wu 2012). We also disregard the “volume” activity data that is available to us which could be a contributing factor for future models. These types of changes might enhance the estimation and make for a more accurate

⁵The papers of Ben Omrane et al. (2019), Andersen et al. (2003) and Fatum, Hutchison, and Wu (2012) among others use the 5 minute window.

representation of the true path. We have also shown that the data collection procedure can benefit from improvements. A meticulous selection of the time window considered and whether it should be fixed to a specific amount of time, as 5 minutes (like in this study), or chosen to vary depending on the conditions could vastly improve the quality of the analysis.

Specifically, the prior for the STVP algorithm is easily adjustable using the ideas of Young (2011) or otherwise and a much better representation of the β_t path would be achievable by having a higher quality one. Most notably, a prior that would place a limit whereby the β_t could not change in sign. If it was discovered that previous surprises affect future ones, the use of a prior other than the 0 mean random walk could also be justified.

Finally, if the One-Step ahead forecasts were to be the priority, the emphasis should of course be placed on minimizing a loss function and thereby reducing irreducible and reducible errors alike. A Machine-Learning approach with algorithms designed specifically for prediction are most likely better suited to this purpose. The time dependency of the problem would nevertheless add to the complexity of such an algorithm and it would be worth considering using the estimators of this study as possible predictors.

7 Appendix

7.1 Parameter Paths

The following path estimations should be interpreted as follows: a one standard deviation unanticipated positive change in the economic variable S_t results in an appreciation or depreciation in the exchange rate of the relevant currency pair by R_t amount of pips or basis points.

7.2 Stochastic Recursive Least Squares Algorithm (SRLS)

1. $\hat{\alpha}_t = \hat{\alpha}_{t-1} + g_t(R_t - S_t^T \hat{\alpha}_{t-1})$
2. $g_t = P_{t-1}^* S_t (\hat{\sigma}^2 + S_t^T P_{t-1}^* S_t)^{-1}$
3. $P_t^* = P_{t-1}^* - g_t S_t^T P_{t-1}^*$

7.3 Standard Recursive Time Variable Parameter Algorithm (STVP)

In the case of this study, it is assumed that the parameter follows a simple random walk. As a result, $A = D = I$. A prior value that represents a 25% change per observation is chosen for the diagonals of Q_a .

Prediction (Prior)

1. $\hat{\alpha}_t | \hat{\alpha}_{t-1} = A \alpha_{t-1}$
2. $P_t^* | P_{t-1}^* = A P_{t-1}^* A^T + D Q_a D^T$

Correction (Posterior)

3. $\hat{\alpha}_t = \hat{\alpha}_t | \hat{\alpha}_{t-1} + g_t(R_t - S_t^T (\hat{\alpha}_t | \hat{\alpha}_{t-1}))$
4. $g_t = (P_t^* | P_{t-1}^*) S_t (\hat{\sigma}^2 + S_t^T (P_t^* | P_{t-1}^*))^{-1}$
5. $P_t^* = P_t^* | P_{t-1}^* - g_t S_t^T (P_t^* | P_{t-1}^*)$

7.4 Steps to obtain qLL statistic

1. Compute the OLS residuals $\hat{\varepsilon}_t$ by regressing R_t on S_t, Z_t ;
2. Construct a consistent estimator \hat{V}_X of the $k * k$ long-run covariance matrix of $S_t \varepsilon_t$. When ε_t can be assumed uncorrelated, a natural choice is the heteroscedasticity robust estimator $\hat{V}_X = T^{-1} \sum_{t=1}^T X_t X_t' \varepsilon_t^2$

Figure 9: Note: 1 Std Dev is +0.605% greater than expected. Currency pair: USD/CAD.

Figure 10: Note: 1 Std Dev is +0.229% greater than expected. Currency pair: USD/CAD.

Figure 11: Note: 1 Std Dev is +0.569% greater than expected. Currency pair: AUD/USD.

Figure 12: Note: 1 Std Dev is +0.229% greater than expected. Currency pair: AUD/USD.

Figure 13: Note: 1 Std Dev is +0.117% greater than expected. Currency pair: USD/CHF.

Figure 14: Note: 1 Std Dev is +0.173% greater than expected. Currency pair: GBP/USD.

Figure 15: Note: 1 Std Dev is +0.206% greater than expected. Currency pair: NZD/USD.

Figure 16: Note: 1 Std Dev is +66.5 thousand more people than expected. Currency pair: USDCHF.

3. Compute $\hat{U}_t = \hat{V}_X^{-1/2} X_t \hat{\varepsilon}_t$ and denote the k elements of \hat{U}_t by $\hat{U}_{t,i}$, $i = 1, \dots, k$.
4. For each series $\hat{U}_{t,i}$, compute a new series, $\hat{w}_{t,i}$ via $w_{t,i} = \bar{r}\hat{w}_{t-1,i} + \Delta\hat{U}_{t,i}$, and $\hat{w}_{1,i} = \hat{U}_{1,i}$, where $\bar{r} = 1 - 10/T$.
5. Compute the squared residuals from OLS regressions of $\hat{w}_{t,i}$ on \bar{r}^t individually, and sum all of those over $i = 1, \dots, k$.
6. Multiply this sum of sum of squared residuals by \bar{r} , and subtract $\sum_{i=1}^k \sum_{t=1}^T (\hat{U}_{t,i})^2$

7.5 Steps to obtain WAR minimization path

1. For $t = 1, \dots, T$, let a_t and b_t be the first p elements of $\hat{H}^{-1}s_t(\hat{\theta})$ and $\hat{H}\hat{V}^{-1}s_t(\hat{\theta})$ respectively.
2. For $c_i \in C = 0, 5, 10, \dots, 50$, $i = 1, \dots, 11$ compute
 - (a) $r_i = 1 - c_i/T$, $z_{i,1} = x_1$ and $z_{i,t} = r_i z_{i,t-1} + x_t - x_{t-1}$, $t = 2, \dots, T$;
 - (b) the residuals $\{\tilde{z}_{i,t}\}_{t=1}^T$ of a linear regression of $\{z_{i,t}\}_{t=1}^T$ on $\{r_i^{t-1} I_p\}_{t=1}^T$
 - (c) $\bar{z}_{i,T} = \tilde{z}_{i,T}$, and $\bar{z}_{i,t} = r_i \bar{z}_{i,t+1} + \tilde{z}_{i,t} - \tilde{z}_{i,t+1}$, $t = 1, \dots, T-1$;
 - (d) $\{\hat{\beta}_{i,t}\}_{t=1}^T = \{\hat{\theta} + a_t - r_i \bar{z}_{i,t}\}_{t=1}^T$;
 - (e) $qLL(c_i) = \sum_{t=1}^T (r_i) \bar{z}_{i,t} - a_t) \tilde{b}_t$ and $\tilde{w}_i = \sqrt{T(1 - r_i^2) r_i^{T-1} / (1 - r_i^{2T})} e^{-\frac{1}{2} qLL(c_i)}$ (set $\tilde{w}_0 = 1$)
3. Compute $w_i = \tilde{w}_i / \sum_{j=1}^{11} \tilde{w}_j$.
4. The parameter path estimator is given by $\{\hat{\beta}_t\}_{t=1}^T = \{\sum_{i=1}^{11} w_i \hat{\beta}_{i,t}\}_{t=1}^T$.
5. The statistic $qLL(10)$ tests the null hypothesis of stability of β and rejects for small values. Critical values depend on p and are tabulated in Table 1 of Elliott and Müller (2006) and 4.

7.6 Variance for credible intervals for the WAR path

$$\Omega_t = \sum_{i=1}^{10} w_i (T^{-1} \hat{S}_\beta \kappa_t(c_i) + (\hat{\beta}_{i,t} - \hat{\beta}_t)(\hat{\beta}_{i,t} - \hat{\beta}_t)'), \quad \kappa_t(c) = \frac{c(1+e^{2c}+e^{2ct/T}+e^{2c(1-t/T)})}{2e^{2c}-2}$$
